Recently, there is a growing interest in development of a bio-inspired artificial muscle that can be controlled like a living body. In a living body, the motility of cells called muscle fibers caused by contractile protein is a mechanical principle that moves various body parts, and is widely used in the field of industrial robots, automobiles, medical robots, etc. A general artificial muscle is developed to mimic the cell excitation and contraction mechanism of the muscle fiber. Here, it is known that the muscle fiber has myofibrils, which are the main components that determine the contractile property. In order to mimic the muscle excitation and contraction mechanism, a natural muscle is generally used. However, the natural muscle has disadvantages in that its excitation and contraction strength are very low, the speed and direction of movement are non-linear, and a smart control method is difficult to develop. For example, it is difficult to imitate motion of a muscle having high excitation and contraction strength of 80% to the muscle having low excitation and contraction strength of 3%, and it is very difficult to imitate the nonlinear movement characteristics due to a parallel arrangement of cells. Accordingly, various attempts have been made to develop an artificial muscle having a structure different from that of the natural muscle. However, a muscle having a structure and movement properties similar to the muscle fiber of a natural muscle is yet to be developed. Increased 1H-MRS signal intensity of metabolites in the temporal lobe due to valproate-induced tremor. This study reports on the 1H magnetic resonance (MR) spectroscopic findings in the context of pharmaco-stimulation, using the 1H MR spectroscopy technique to examine the pathophysiology of tremor in a patient with pharmacologic treatment-induced tremor. 1H MR spectroscopy was performed on the frontal and parietal lobes and the cerebellum in a 42-year-old woman with pharmacologically induced tremor.
